# IPs with Bounded Resources

Let  $IP[pc=1]$  be the languages decidable via IPs where prover sends 1 bit only.

Is  $IP[pc=1]$  trivial (contained in P)?

Probably no, since  $QNI \in IP[pc=1]$  and  $QNI$  is not known to be in P.

$\Rightarrow$  even IPs with small communication can decide non-trivial languages.

Could we hope for  $SAT \in IP[pc = o(n)]$  ( $pc$  is sublinear in #vars)?

Note that  $SAT \in NP \subseteq IP$  so the question is about whether there exists an IP for SAT that provides some efficiency benefits over the trivial IP.

To formally study this question we consider:

$IP[pc, vc, vr]$  = "languages decidable by IP where prover sends  $pc$  bits, verifier sends  $vc$  bits, and verifier uses  $vr$  random bits (& any # of rounds)"

$AM[pc, vc, vr]$  = "similar but with public-coin IPs"

We will learn about several limitations of IPs with bounded resources.

# Limitations of Bounded Resources (1/2)

Easier case: prover communication and verifier communication are bounded.

- If we additionally bound the verifier randomness then we can decide the language in deterministic exponential time.

theorem 1:  $IP[p_c, v_c, v_r] \subseteq DTIME(2^{O(p_c + v_c + v_r)} \text{poly}(n))$

- Else we can decide the language in probabilistic exponential time.

theorem 2:  $IP[p_c, v_c, *] \subseteq BPTIME(2^{O(p_c + v_c)} \text{poly}(n))$

We prove both theorems today.

$\Rightarrow$  there is a relation between communication complexity of IP and the time complexity of the language it decides

Example for 3SAT: it's unlikely that  $3SAT \in IP[p_c = o(n), v_c = o(n)]$

because that would imply that  $3SAT \in BPTIME(2^{o(n)})$ ,

which contradicts the (randomized) Exponential Time Hypothesis (rETH).

# Limitations of Bounded Resources (2/2)

Harder case: prover communication only is bounded.

- Assuming perfect completeness, we can non-deterministically decide the complement.

theorem 3:  $IP[\epsilon_c = 0, pc, *, *] \subseteq coNTIME(2^{O(pc)} \cdot poly(n))$

- Without perfect completeness, it's more complicated.

theorem 4:  $AM[pc, *, *] \subseteq BPTIME(2^{O(pc \cdot \log pc)} poly(n))$

theorem 5:  $IP[pc, *, *] \subseteq BPTIME(2^{O(pc \cdot \log pc)} poly(n))^{NP}$

theorem 6:  $IP[k, pc, *, *] \subseteq coAM(\text{rounds} = O(k), pc' = 2^{pc} \cdot poly(k^k, n))$

we don't prove these in lecture

Example for  $QNI$ :

We know that  $QNI \in IP[pc=1]$  and  $QNI \in AM[pc=O(n^2)]$ .

But we should not expect that  $QNI \in AM[pc = o(\frac{\log n}{\log \log n})]$  unless  $QNI \in P$ .

prover sends pre-image  $H \in \{0,1\}^{n^2}$   
& isomorphism  $\phi: [n] \rightarrow [n]$

# Game Tree

A transcript (of interaction) is a tuple  $(a_1, b_1, \dots, a_k, b_k)$ .

An augmented transcript is  $(a_1, b_1, \dots, a_k, b_k, r)$  where  $r$  is verifier randomness.

Fix a verifier  $V$  and instance  $x$ .

The game tree  $T = T(V, x)$  of  $V(x)$  is the tree of all possible augmented transcripts  $\rightarrow$

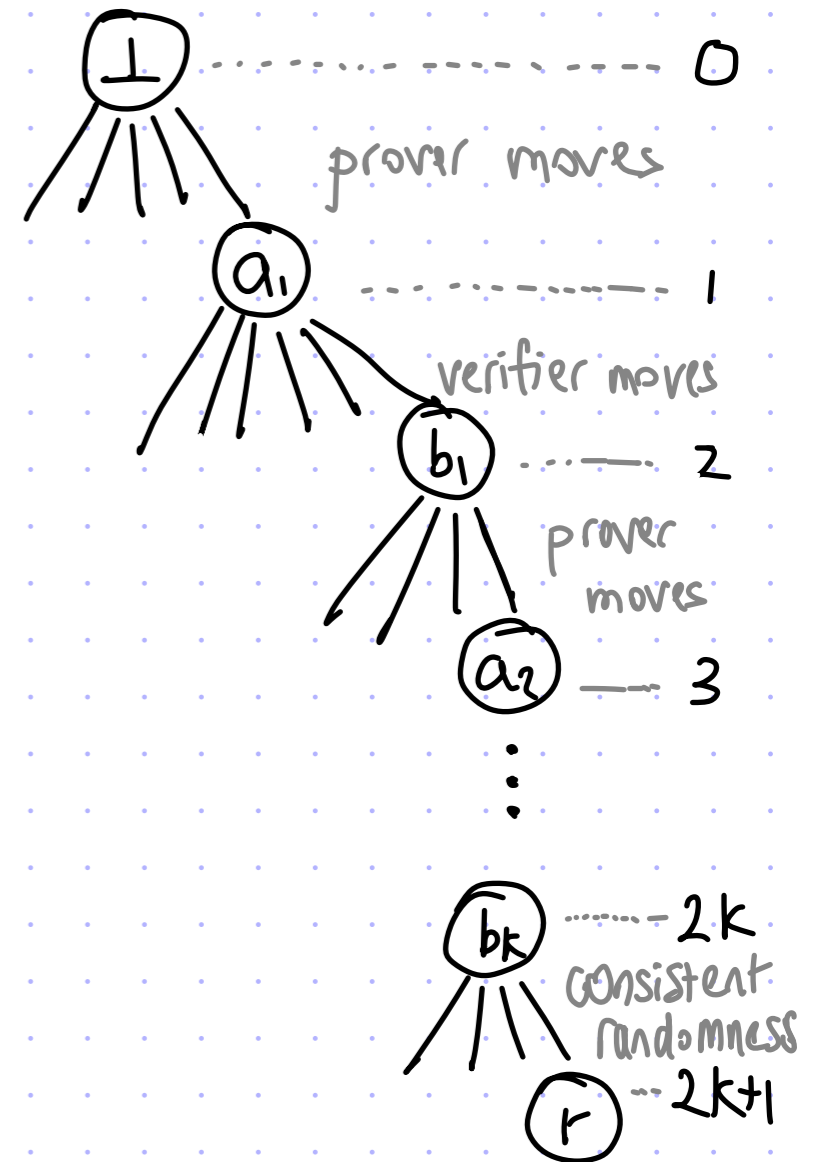

For  $i = 0, 1, \dots, k-1$ :

- prover moves at level  $2i$
- verifier moves at level  $2i+1$

Edges from  $2i$  to  $2i+1$  are possible moves by prover.

Edges from  $2i+1$  to  $2(i+1)$  are possible moves by verifier.

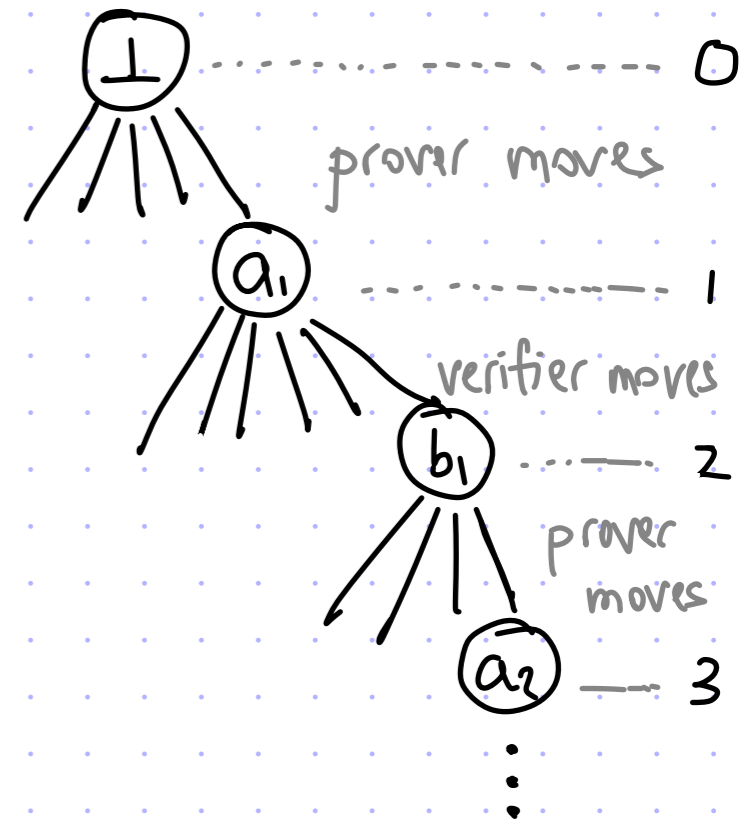

Edges from  $2k$  to  $2k+1$  are possible random strings consistent with transcript.

# Approximating the Value Suffices

def:  $\text{val}(T)$  is the value of the root, which is recursively computed as follows:

- value of a leaf node at location  $(a_1, b_1, \dots, a_k, b_k, r)$  is the bit  $V(x, a_1, \dots, a_k; r) \in \{0, 1\}$
- value of an internal node at level  $2i$  is the **maximum of its children's values** [prover maximizes]
- value of an internal node at level  $2i+1$  is the **weighted average of its children's values** where the weights are the probabilities of each verifier message [this includes second to last layer where the randomness  $r$  can be viewed as a fictitious final verifier message]

If  $x \in L$  then  $\text{val}(T) \geq \frac{2}{3}$ , else if  $x \notin L$  then  $\text{val}(T) \leq \frac{1}{3}$ . So to decide if  $x \in L$  or  $x \notin L$  it suffices to approximate  $\text{val}(T)$  to within  $\pm \frac{1}{6}$ .

Note: can compute  $\text{val}(T)$  in  $\text{poly}(n)$  space and  $\text{exp}(\text{poly}(n))$  time.

Today we are interested in **time complexity to approximate  $\text{val}(T)$** .

**Theorem 1:**  $\text{IP}[pc, vc, vr] \subseteq \text{DTIME}(2^{O(pc+vc+vr)} \text{poly}(n))$

Let  $c = pc + vc + vr$  be a bound on communication complexity and randomness.

The number of nodes in  $T$  is  $2^{O(c)}$  because there are  $\leq 2^{pc+vc}$  possible transcripts and each has  $\leq 2^{vr}$  possible augmentations, yielding  $\leq 2^{pc+vc+vr+1}$  leaves.

Hence, can compute  $\text{val}(T)$  (exactly) in  $2^{O(c)} \text{poly}(n)$  time, by writing out the tree explicitly and following the recursive computation.

Note: we can actually set  $c = pc + vr$  since the number of augmented transcripts can be bounded by  $2^{pc} \cdot 2^{vr}$ .

Note: how do we compute the probabilities of verifier messages?

Associate to each node where verifier moves the set of all random strings consistent with transcript so far. To generate the probabilities iterate over this set, which will partition set according to verifier's move.

[We are not partitioning randomness when prover moves.

Hence the same randomness  $r$  may appear in more than 1 leaf.]

Theorem 2:  $IP[p_c, v_c, *] \subseteq BPTIME(2^{O(p_c+v_c)} \text{poly}(n))$

Let  $c = p_c + v_c$  be a bound on communication only.

There are still  $\leq 2^c$  possible transcripts. (Hence  $\leq 2^{O(c)}$  internal nodes.)

But now each transcript may have  $2^{\text{poly}(n)}$  augmentations.

Hence, we **cannot construct  $T$  in the allotted time**  $(2^{O(c)} \text{poly}(n))$ , nor compute the probabilities of verifier messages inside the tree.

Instead: will use randomness to approximate  $\text{val}(T)$  in  $2^{O(c)} \text{poly}(n)$  time

Probabilistic algorithm:

1. sample  $R = \{r_1, \dots, r_m\}$  independently in  $\{0,1\}^{vr}$ , with  $m = \Theta(2^c \cdot c)$
2. compute  $\text{val}(T[R])$  where  $T[R]$  is the **residual game tree** obtained by omitting nodes inconsistent with  $R$  (and adjusting weights)

The algorithm runs in time  $2^{O(c)} \text{poly}(n)$  because  $|T[R]| = 2^{O(c)} \cdot |R| = 2^{O(c)}$ .

We are left to argue correctness.

lemma:  $\Pr_R \left[ \left| \text{val}(T[R]) - \text{val}(T) \right| \leq \frac{1}{10} \right] \geq \frac{99}{100}$ .

proof: A concentration argument applied to the right random variables.

Define  $V^R$  to be the verifier  $V$  restricted to sample randomness in  $R$  rather than  $\{0,1\}^{vr}$ .

Observe that:

$\text{val}(T[R]) = \left[ \begin{array}{l} \text{maximum acceptance probability of } V^R(x) \text{ when} \\ \text{interacting with any prover strategy} \end{array} \right]$ .

Fix a prover strategy  $\tilde{P}$  and define:

$$\begin{aligned} \Delta(\tilde{P}, R) &:= \Pr_{r \leftarrow R} [\langle \tilde{P}, V(x; r) \rangle = 1] - \Pr_{r \leftarrow \{0,1\}^{vr}} [\langle \tilde{P}, V(x; r) \rangle = 1] \\ &= \underbrace{\Pr [\langle \tilde{P}, V^R(x) \rangle = 1]}_{\text{depends on } R} - \underbrace{\Pr [\langle \tilde{P}, V(x) \rangle = 1]}_{\text{independent of } R}. \end{aligned}$$

We now argue that  $|\Delta(\tilde{P}, R)|$  is small w.h.p. over the choice of  $R$ .

claim:  $\forall \tilde{P}, \Pr_R \left[ |\Delta(\tilde{P}, R)| > \frac{1}{10} \right] \leq 2 \cdot e^{-2 \cdot (\frac{1}{10})^2 \cdot m}$ .

proof:

Define  $z_i := \langle \tilde{P}, V(x; r_i) \rangle$  where  $r_i$  is  $i$ -th random string in  $R$ .

The random variables  $z_1, \dots, z_m$  are i.i.d. because  $r_1, \dots, r_m$  are.

Moreover: •  $\mathbb{E}[z_i] = \Pr \left[ \langle \tilde{P}, V(x) \rangle = 1 \right]$  as each  $r_i$  is random in  $\{0, 1\}^{vr}$

•  $\frac{z_1 + \dots + z_m}{m} = \Pr \left[ \langle \tilde{P}, V^R(x) \rangle = 1 \right]$

$X_1, \dots, X_m$  iid in  $[0, 1]$   
 $\Pr \left[ |\bar{X} - \mathbb{E}[X_i]| > \varepsilon \right] \leq 2 \cdot e^{-2 \cdot \varepsilon^2 \cdot m}$

We can conclude the proof by a Chernoff bound:

$$\begin{aligned} \Pr_R \left[ |\Delta(\tilde{P}, R)| > \frac{1}{10} \right] &= \Pr_R \left[ \left| \Pr \left[ \langle \tilde{P}, V^R(x) \rangle = 1 \right] - \Pr \left[ \langle \tilde{P}, V(x) \rangle = 1 \right] \right| > \frac{1}{10} \right] \\ &= \Pr_R \left[ \left| \frac{z_1 + \dots + z_m}{m} - \mathbb{E}[z_1] \right| > \frac{1}{10} \right] \leq 2 \cdot e^{-2 \cdot (\frac{1}{10})^2 \cdot m} \quad \blacksquare \end{aligned}$$

claim:  $\forall \tilde{P}, \Pr_R [|\Delta(\tilde{P}, R)| > \frac{1}{10}] \leq 2 \cdot e^{-2 \cdot (\frac{1}{10})^2 \cdot m}$ . ✓

Any prover  $\tilde{P}$  is a function from transcript so far to next message.  
So there are at most  $(2^c)^{2^c} = 2^{c \cdot 2^c}$  provers (as input and output sizes are  $\leq 2^c$ ).

By a union bound on all such provers, and taking  $m = \Theta(2^c \cdot c)$  large enough,

$$\Pr_R [\exists \tilde{P}: |\Delta(\tilde{P}, R)| > \frac{1}{10}] \leq \sum_{\tilde{P}} \Pr_R [|\Delta(\tilde{P}, R)| > \frac{1}{10}] \leq 2^{c \cdot 2^c} \cdot 2 \cdot e^{-2 \cdot (\frac{1}{10})^2 \cdot m} < \frac{1}{100}.$$

We conclude the proof by noting that:

$$\Pr_R [|\text{val}(T[R]) - \text{val}(T)| > \frac{1}{10}] \leq \Pr_R [\exists \tilde{P}: |\Delta(\tilde{P}, R)| > \frac{1}{10}] (< \frac{1}{100}).$$

Indeed, for any choice of  $R$ , the event on the left implies the event on the right:

- $\text{val}(T[R]) > \text{val}(T) + \frac{1}{10} \rightarrow \Pr_c [\langle P_R^*, v^R(x) \rangle = 1] > \Pr_c [\langle P^*, v(x) \rangle = 1] + \frac{1}{10} \geq \Pr_c [\langle P_R^*, v(x) \rangle = 1] + \frac{1}{10}$
- $\text{val}(T) > \text{val}(T[R]) + \frac{1}{10} \rightarrow \Pr_c [\langle P^*, v(x) \rangle = 1] > \Pr_c [\langle P_R^*, v^R(x) \rangle = 1] + \frac{1}{10} \geq \Pr_c [\langle P^*, v^R(x) \rangle = 1] + \frac{1}{10}$
