

Ethical issues in Covid policy

M. Fleurbaey

August 13, 2020

Outline

- 1 Welfare evaluation
- 2 Three policy questions

Two approaches

- Cost-benefit analysis with value of statistical life
- Social welfare analysis based on distribution of individual well-being

Welfare evaluation: first approach

- Cost-benefit analysis:
 - $VSL \times \text{Total Deaths Avoided} - \text{Income Loss}$
 - $VSLY \times \text{Total Life-Years Saved} - \text{Income Loss}$
 - $VSLY \times \text{Total QALYs Saved} - \text{Income Loss}$
- Orders of magnitude:
 - $VSL = 150 \text{ income/capita}$, $VSLY = 3 \text{ income/capita}$
 - Total Deaths: 1% of population without policy, 0.1% with policy: 0.9% gain
 - Life-years lost per death: 10 years
 - $VSL \times \text{Total Deaths Avoided} = 135\% \text{ income}$
 - $VSLY \times \text{Total Life-Years Saved} = 27\% \text{ income}$

Welfare evaluation: second approach

- Individual well-being (“utility”) $U = \left(\frac{YL}{85}\right) \left(\frac{L}{85}\right)^\alpha$ where Y is yearly income, L is longevity, and 85 is a reference longevity
- The product YL is the total lifetime income of someone who earns Y every year for L years
- $U =$ “equivalent income”, i.e., amount of yearly income Y^* that would make the individual indifferent between his current life and a hypothetical life in which he would earn Y^* for 85 years:

$$\left(\frac{YL}{85}\right) \left(\frac{L}{85}\right)^\alpha = \left(\frac{Y^*85}{85}\right) \left(\frac{85}{85}\right)^\alpha = Y^*.$$

- This is just a (convex) transform of the more usual $LY^{\frac{1}{1+\alpha}}$
- To obtain WTP for L in terms of YL equal to VSLY, calibrate $\alpha = VSLY/Y = 3$

Welfare evaluation: SWF cont'd

- Social welfare is the “equally-distributed equivalent” (EDE):

$$SW = \left(\frac{1}{5} \sum_i U_i^{1-\eta} \right)^{\frac{1}{1-\eta}}$$

- Thanks to homogeneity, evaluations do not depend on reference longevity (85)
- Final individual well-being:
 - survivors: $\left(\frac{YL - Y\Lambda}{85} \right) \left(\frac{L}{85} \right)^\alpha$ where Λ is economic loss in proportion of annual income
 - dead: $\left(\frac{YL - Y\Lambda}{85} \right) \left(\frac{L - LE}{85} \right)^\alpha$ where LE is years lost (10)
 - variant: survivors $\left(\frac{Y^+L - Y^+\Lambda}{85} \right) \left(\frac{L}{85} \right)^\alpha$, dead: $\left(\frac{YL}{85} \right) \left(\frac{L^+ - LE}{85} \right)^\alpha$
(most survivors are young who benefit from economic growth; most victims are pensioners and do not live to bear the full economic costs)

Which approach is better?

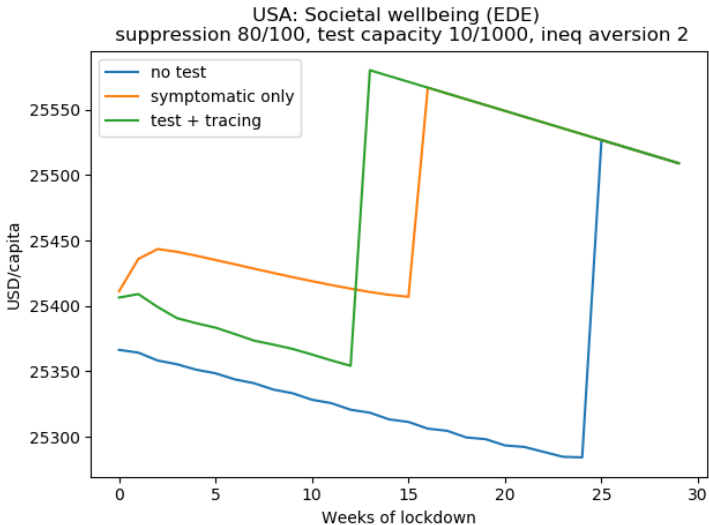

- Cost-benefit analysis ignores the distribution and makes a linear approximation (from marginal risk reduction to WTP for a year, or even a life)
- SWF approach alleviates these two problems, but requires more data (inequalities in initial incomes and longevity, in economic cost and in fatalities)
- The equivalent income utility scale, combined with $\eta = 0$ (i.e., no inequality aversion), addresses only the non-linearity issue: interesting for comparison with cost-benefit analysis (scoop: makes no difference)

Three policy questions

- 1 Suppression vs. control
- 2 How long the initial lockdown?
- 3 When to start the policy (eradication or control)?

How long should the first lockdown be?

Assumption: no treatment, no vaccine, no repeated lockdown afterward

When to start the policy?

Economic cost: 0.5 elasticity with respect to income

USA: Societal wellbeing

contact reduct. 70/100, contagion reduct. 40/100, fatality threshold 7000,
inequality aversion 2, economic impacts 0.5

Conclusion: lessons?

- Simple SWF analysis is possible. Too simple? Other groups, other inequalities (e.g., social distancing unequally possible)
- Pandemic dynamics is interesting: contact changes people - "that's the story of life"
 - social externalities: human beings are ultrasocial, dependent on others
 - implies vulnerability and resilience, multiple equilibria and multiplier effects
- Policy challenge: the jackpot is very painful to attain - but the blessed who reach it are better off in ALL respects, much fewer deaths and less economic cost

Contamination as a fall into sickness

Stratification under Pandemic Game

$$\alpha^+ = 0.0, \alpha^- = 0.0, \beta^+ = 0.0, \beta^- = 0.0, \gamma^+ = 0.0, \gamma^- = 0.05, l^{++} = 0.33, \\ s = 20, r^+ = 0.50, r^- = 0.50$$

Contamination as antibody learning

Stratification under Pandemic Game

$$\alpha^+ = 0.0, \alpha^- = 0.0, \beta^+ = 0.0, \beta^- = 0.0, \gamma^+ = 0.0, \gamma^- = 0.05, l^{++} = 0.33, \\ s = 20, r^+ = 0.50, r^- = 0.50$$
